NACA WARTIME REPORTS are reprints of papers originally issued to provide rapid distribution of advance research results to an authorized group requiring them for the war effort. They were previously held under a security status but are now unclassified. Some of these reports were not technically edited. All have been reproduced without change in order to expedite general distribution.

ADVANCE CONFIDENTIAL REPORT

WIND-TUNNEL INVESTIGATION OF EFFECTS OF A PUSHER

PROPELLER ON LIFT, PROFILE DRAG, PRESSURE

DISTRIBUTION, AND BOUNDARY-LAYER

TRANSITION OF A FLAPPED WING

By Carl A. Sandahl

SUMMARY

Some of the effects of pusher-propeller operation on the aerodynamic characteristics of a flapped wing were measured in the Langley propeller-research tunnel. The effects of propeller operation on the lift and profile drag of the wing, on pressure distribution, and on the position of boundary-layer transition were obtained. The results indicated that, at fixed angles of attack and with flaps deflected, the wing lift increased appreciably with increasing thrust coefficient. With flaps retracted, no appreciable increase in lift with increases in thrust coefficient was measured. Chordwise pressure distributions at several spanwise stations indicated that the effect of propeller operation was greatest in the region immediately ahead of the propeller and that the effect extended outboard from the propeller axis for about 2.5 propeller radii. Measurements of boundary-layer velocity on the forward part of the upper surface of the wing showed no appreciable shift of transition in the range of thrust coefficients investigated.

INTRODUCTION

As part of a study of the efficiency of a pusher propeller behind a low-drag wing, some measurements relating to the effects of the propeller inflow on the aerodynamic characteristics of the wing were made in the Langley propeller-research tunnel. The data, which are presented herein, show the effects of propeller operation

on the lift of the wing with flaps retracted and deflected, on the pressure distribution, on the section profile drag, and on the position of boundary-layer transition on the upper surface.

APPARATUS AND TESTS

The general arrangement of the model used in the present investigation is shown in figure 1 and the model configurations, in figure 2. The geometric characteristics of the model are as follows:

Wing area with flap retracted, square feet	77.27
Wing span, feet	16.06
Wing chord with flap retracted, feet	4.932
Aspect ratio	3.34
Airfoil section	NACA 63,4-420 (approx.)
Flap chord, feet	1.32
Propeller diameter, feet	4.0

The wing was constructed of wood covered with fiberboard. For the tests to determine boundary-layer transition, the wing was carefully sanded and waxed; however, for the other tests, including the measurements of profile drag, the wing was considerably less smooth, particularly at the leading edge. Full-span landing flaps of single-slotted, double-slotted, and split types were used with the wing. The nacelle was faired into the wing and no provision was made for air flow through the nacelle.

The three-blade propeller with a 4-foot diameter was a Hamilton-Standard 6101 design of modified pitch distribution and right-hand rotation. (See fig. 3.) The propeller was driven by a variable-speed variable-frequency induction motor rated at 70 horsepower at 3000 rpm. The propeller blades were set at 22.5° at the 0.75-radius station. The maximum propeller rotational speed was 3000 rpm, and the maximum wind-tunnel speed was 30 miles per hour. Tunnel speeds lower than the maximum were necessary in developing the higher values of thrust coefficient of these tests. The range of thrust coefficients used was extended to values considerably higher than those of normal flight in order to accentuate the effects of propeller operation on the aerodynamic characteristics of the wing.

Lifts were measured over a range of thrust loadings at flap deflections of 0° , 20° , and 40° and at geometric angles of attack of 0° , 3° , 6° , and 9° . Pressure distribution, profile drag, and boundary-layer transition were measured only with the flap retracted.

The section profile-drag coefficient was measured at three spanwise stations in the vicinity of the propeller. (See fig. 1.) The limited space between the wing and the propeller necessitated mounting the rake immediately behind the trailing edge as shown in figure 4. Both static and total pressure were measured.

The pressure distribution over the wing was measured with a pressure belt constructed of 0.040-inch copper tubes soldered together as shown in figure 5. The excess solder was scraped from the surface of the belt, and an orifice with a diameter of 0.020 inch was drilled into the wall of each tube at the desired chordwise locations. The belt was then formed to the wing section and mounted on the surface.

Boundary-layer transition was determined from measurements in the boundary layer over the forward 60 percent of the upper surface of the wing at seven spanwise stations. (See fig. 1.) The total pressure in the boundary layer was measured with 0.040-inch stainless steel tubes flattened to an inside height of 0.006 inch. (See fig. 6.) The geometric centers of the tubes were set 0.011 inch above the wing surface. The velocity in the boundary layer was calculated by using the total pressure in the boundary layer and the local static pressure previously measured with the pressure belt.

SYMBOLS

C_{L_T} total lift coefficient of wing with propeller
operating $\left(\frac{\text{Resultant vertical force}}{q_0 S} \right)$

ΔC_{L_p} increment of lift coefficient due to propeller
thrust inclination $\left(\frac{\text{Vertical component of propeller axial force}}{q_0 S} \right)$
 $= \frac{T_e \sin \alpha}{q_0 S}$

C_L	net lift coefficient of wing $(C_{L_T} - \Delta C_{L_P})$
c_{d_o}	section profile-drag coefficient $\left(\frac{\text{Section profile drag}}{q_o c} \right)$
T_c	effective thrust disk-loading coefficient based on propeller disk area $\left(\frac{T_e}{\rho V_o^2 D^2} \right)$
T_e	effective thrust, pounds
D	propeller diameter, feet
V_o	free-stream velocity, feet per second
u	velocity in surface direction inside boundary layer, feet per second
S	wing area, square feet
c	wing chord, feet
ρ	mass density of air, slug per cubic foot
α	angle of attack, degrees; measured between thrust line (coincident with chord line) and relative wind; corrected for jet boundary
δ_f	flap deflection, degrees
x	distance from leading edge of wing parallel to chord line
y	lateral distance from plane of symmetry
q_o	free-stream dynamic pressure $\left(\frac{1}{2} \rho V_o^2 \right)$
p	local static pressure on wing
p_o	free-stream static pressure

\bar{P} average chordwise pressure ratio $\left(\frac{p - p_o}{q_o} \right)$

RESULTS AND DISCUSSION

The results of this investigation are presented in four sections showing the effects of propeller operation on (1) lift, (2) chordwise and spanwise pressure distribution, (3) boundary-layer transition, and (4) profile drag. The data are expressed in nondimensional coefficients and have been corrected for jet-boundary effects.

In a preliminary comparison, it was found that lift with propeller operating at $T_o = 0$ would agree with lift for the propeller removed within experimental accuracy. The lift coefficients at $T_o = 0$ in this report may therefore be considered as propeller-removed values.

Effect of propeller operation on lift.—Lift with power on is considered to have four components: (1) the lift of the wing at $T_o = 0$, (2) the increment of lift of the wing caused by operation of the propeller, (3) the vertical component of propeller axial force, and (4) the propeller normal force. The maximum propeller normal force developed in these tests is estimated to be within the scatter of experimental points. Component (2), the increment of lift, is then obtained by deducting components (1) and (3) from the measured resultant vertical force. In evaluating component (3), the propeller axial force was assumed to be equal to the effective thrust and independent of angle of attack at a given value of advance-diameter ratio.

The variation of total lift coefficient C_{LT} with thrust disk-loading coefficient T_o is given in figure 7 for several angles of attack and several flap deflections. In correcting the angles of attack for jet-boundary effects, the total lift coefficient C_{LT} at $T_o = 1.0$ was used. This simplification introduced inaccuracies in angle of attack of the order of $\pm 0.3^\circ$ and corresponding changes in total lift coefficient of ± 0.012 , which is within the scatter of the experimental points. The vertical component of propeller axial force has been

deducted from the faired curves of total lift coefficient of figure 7, and the resulting net lift coefficient is cross-plotted against angle of attack at three values of T_c in figure 8. In this figure, the angle of attack has been corrected by using the total lift coefficient at each value of T_c . The curves of figure 8 indicate that the slope of the lift curve is approximately independent of T_c . With flaps retracted, propeller operation - even at high thrust coefficients - did not appreciably affect the wing lift (fig. 8(a)). With flaps deflected, however, the lift increased with increasing T_c . The increment of wing lift resulting from propeller operation is the difference in lift between the curves for $T_c = 0$ and curves for the propeller operating in figure 8 and is attributed to only the propeller inflow. It is noted that a British investigation (reference 1) shows larger increases in lift due to propeller operation than were measured in the present investigation.

Less lift was obtained at $T_c = 0$ with the double than with the single slotted flap. The difference may have been caused by incorrect design of the double slotted flap.

Effect of propeller operation on pressure distribution. - The chordwise pressure distribution at several spanwise stations and several values of T_c is given in figure 9. The maximum observed decrease in local pressure associated with propeller operation occurred near the trailing edge at $\frac{y}{c} = 0.20$, the point of measurement nearest the thrust center line. The pressure decrease at $\delta_f = 0^\circ$ was approximately the same over the upper and lower surfaces, an indication that there was no appreciable change in lift. This result is in agreement with the results of the force tests given in figure 8(a).

From figure 10, in which the average chordwise pressure ratio is plotted against spanwise station, it may be noted that the propeller effect extended outboard to $\frac{y}{c} \approx 1.0$, or about 2.5 propeller radii from the propeller axis.

Effect of propeller operation on boundary-layer transition. - The ratio of the velocity at a constant height (0.011 in.) in the boundary layer to free-stream velocity u/V_0 is plotted as a function of the distance from the leading edge x/c in figure 11 for several thrust coefficients and test velocities. No appreciable shift in transition associated with propeller operation or with Reynolds number was measured. This result is in agreement with reference 2.

Effect of propeller operation on section profile drag. - The section profile-drag coefficient was measured at three spanwise stations in the vicinity of the propeller. (See fig. 1.) The variation of section profile-drag coefficient with thrust disk-loading coefficient is given in figure 12 for three test velocities. The rather high profile-drag coefficients measured at $T_0 = 0$ are attributed to surface roughness near the leading edge, which presumably caused transition to occur much farther forward than with the highly polished surface on which the transition measurements of figure 11 were obtained. Larger increases of section profile-drag coefficient with increasing thrust coefficient occurred than can be accounted for as increased skin friction due to the increased velocity in the propeller inflow. These increases in drag coefficient are probably due to the action of the low-pressure region in front of the propeller in drawing low-energy boundary-layer air from other sections of the wing toward the sections ahead of the survey rake.

CONCLUSIONS

The foregoing analysis of measurements made to determine the effects of pusher-propeller operation on some of the aerodynamic characteristics of a low-drag wing with flaps indicated that:

1. At fixed angles of attack and with flaps deflected, the lift of the wing increased appreciably with increasing thrust coefficient.
2. Changes in pressure distribution over the wing caused by propeller operation were largest immediately ahead of the propeller and extended outboard to approximately 2.5 propeller radii from the propeller axis.

With flaps retracted, no appreciable change in wing lift or span load distribution was measured.

3. No appreciable shift of transition with variation of thrust coefficient was measured.
